Abstract

The Lower Jurassic platform and basinal deposits exposed in the Montagna dei Fiori Anticline (Central Apennines, Italy) are pervasively affected by dolomitization. Based on the integration of field work, petrography, and geochemistry, two fault-related dolomitization events were recognized and interpreted as occurred before and during the Apenninic orogeny, respectively. Fluid inclusion analysis indicates moderate to elevated salinity values of 3.5 to 20.5 and 12.8 to 18.6 eq. wt. % NaCl, in the first and the second event, respectively. The estimated salinities, in combination with $\delta^{18}O$ values and $^{87}Sr/^{86}Sr$ ratios, suggest significant involvement of evaporitic fluids in both events, most likely derived from the underlying Upper Triassic Burano Formation. In addition, the $^{87}Sr/^{86}Sr$ ratios up to 0.70963 suggest the circulation of deep-sourced fluids that interacted with siliciclastics and/or the crystalline basement during the dolomitization events. ~~The first dolomitization event which is also considered as the most pervasive one started prior to the significant burial conditions, as reflected in homogenization temperatures of their fluid inclusions being mostly below about 40-50°C.~~ Two major dolomite types (D1 and D2) were recognized as pertaining to ~~this~~ the first event, both postdated by high amplitude bed-parallel stylolites~~.~~, supporting~~This relationship supports~~ a syn-burial, pre layer-parallel shortening dolomitization~~, interpreted as controlled by the extensional fault pattern affecting the carbonate succession before its involvement in the Apenninic thrust wedge~~. A

possible geodynamic framework for this dolomitization event is Early to Late Jurassic rift-related extensional tectonism. The second dolomitization event (D3, D4 and D5) ~~initiated with a dolomite type (D3)~~is characterized by a ~~slight~~ temperature upturn ~~(up to 73°C), followed by a second type (D4) with markedly higher homogenization temperatures~~ (up to 105°C), and interpreted as associated with the inflow of hydrothermal fluids, possibly related to major changes in the permeability architecture of faults during early- to syn-thrusting and folding activity. ~~Eventually, D4 was overprinted by a late generation of dolomite veins (D5) interpreted as associated with late orogenic extensional faulting in the backlimb of the Montagna dei Fiori Anticline.~~ Based on the timing of deformation in the Montagna dei Fiori Anticline, ~~D3 to D5~~the second dolomitization event likely occurred in Late Miocene to Pliocene times. The findings regarding characteristics and timing of dolomitization here illustrates the long-term controlling role of the eveporitic detachments in dolomitization process. Our data shows the Mg-rich fluids most likely derived from these evaporites may prime the tectonically involved successions for repeated dolomitization, and formation of potential reservoirs in sequential tectonic modifications (extensional vs. compressional).

1 Introduction

Fault-controlled dolomitization has been the focus of attention in many studies during the last decades due to its influential role in modifying the petrophysical properties of rocks and, hence, anisotropy in fluid migration pathways, and, ultimately on reservoir quality (e.g. Purser et al., 1994; Montanez, 1994; Zempolich and Hardie, 1997; Vandeginste et al., 2005; Davies and Smith, 2006; Sharp et al. 2010). The mechanical and hydrological behaviour of fault zones are in turn influenced by fluid-rock interactions and diagenetic modifications (e.g. Gale et al., 2004; Laubach et al., 2010; Clemenzi et al., 2015). It follows that the mutual interplay between fault activity and fluid-driven rock-fluid interaction can trigger dolomitization of carbonates and, consequently, variations in physico-chemical properties of fluids through time and space. Leaking or sealing behaviours of fault zones during deformation are key controls for fault-related fluid circulation. A detailed understanding of such an interplay is thus necessary to improve our capability of making reliable predictions of fault-related dolomitization in carbonate reservoirs. Studying outcrop analogues provides fundamental support to meet this requirement (e.g. Swennen et al., 2012; Dewit et al., 2014; Bistacchi et al., 2015).

The Lower Jurassic to Lower Cretaceous Umbria-Marche passive margin carbonate succession, in the Central Apennines (Italy), is intensely affected by localized dolomitization both in the onshore fold-and-thrust belt and in offshore foredeep and foreland areas (e.g. Murgia et al., 2004; Pierantoni et al., 2013). The dolomitized intervals are well-exposed in the core of the Montagna dei Fiori Anticline ~~(e.g. Ronchi et al., 2003)~~, where the dolomitized Lower Jurassic intervals (Calcare Massiccio, Bugarone and Corniola Formations) and their relationships with fault zones allow to study the mutual influence between deformation structures and dolomitized intervals (Fig. 1). These intervals, known as the Castel Manfrino Dolostones (Crescenti, 1969; Mattei, 1987; Koopman, 1983), have been previously studied by Ronchi et al. (2003) only at its reference section, exposed at the Castel Manfrino location (Fig. 1b), in the central sector of the Montagna dei Fiori Anticline (Fig. 2). A fault-controlled dolomitization model and the relative timing of dolomitization were proposed by ~~Ronchi (2003)~~the latter authors~~.~~ based on the homogenization temperatures obtained from microthermometry of the fluid inclusions, and their relation with the thermal history of the studied area. However, no clear relation between dolomitization and structural evolution of the Montagna dei Fiori Anticline on a local scale was provided to confidently link the occurrence of dolomitization to a particular tectonic event. Moreover, the nature and origin of the dolomitizing fluids were not well constrained. Recent re-evaluation of dolostone distribution in the Montagna dei Fiori Anticline (Storti et al., 2017a), showed that the dimension of the dolomitized geobodies (Fig. 2) is much more significant than what was previously mapped by Mattei (1987). Dolostones are distributed within fault damage zones and in the laterally adjacent carbonate rocks, and in intersection areas between fault sets, for a total area in map view of more than 1.5 km^2 (Storti et al., 2017a).

The structural pattern of the Montagna dei Fiori Anticline documents the overprinting of extensional and contractional deformation along major fault zones. ~~Although challenging, the~~The preserved structural framework in this anticline provides an opportunity to study the direct but complex regional tectonic controls on dolomitization in carbonate successions undergoing multiple deformation events, from rifting to folding and thrusting. This contribution integrates field mapping, new petrographic, geochemical, and microthermometric analyses, with structural studies to characterize the temporal record of fault-controlled diagenetic phases and, more specifically, dolomitization in the carbonatic succession outcropping in the Montagna dei Fiori Anticline. Therefore provides insights into the structural controls on regional fluid flow and their

chemical evolution through time. These findings might be of relevance for exploration and reservoir quality prediction onshore and offshore the Apennines and Southern Alps. Moreover, this work provides additional evidence of the potential influence of fluids derived from evaporitic detachment levels in modifications of geochemical trends and petrophysical properties of the overlying carbonate rocks.

2 Geological setting

The Montagna dei Fiori Anticline is a NNW-SSE striking, thrust-related fold located at the mountain front of the Central Apennines (Fig. 1). The geodynamic evolution of the Apennines is generally known to be the result of the superposition of NE-SW compression (in present-day geographic coordinates), related to the convergence between Eurasia and Africa plates since Late Cretaceous times (Elter et al., 1975; Dewey et al., 1989; Patacca et al., 1992), on a rifting-related tectono-sedimentary architecture produced by Early Jurassic extension (e.g., Centamore et al., 1971). In such a framework, the Central Apennines developed during Miocene to Plio-Pleistocene times (e.g. Parotto and Praturlon, 1975; Barchi et al., 1998; Mazzoli et al., 2002; Bollati et al., 2012).

The Central Apennines involves the Umbria-Marche succession, which essentially includes Triassic to Miocene carbonates and marls, covered by Miocene to Pliocene syn-orogenic clastic sediments (Fig. 1). The pre-orogenic succession, from bottom to top, includes Late Triassic evaporites, dolomites and limestones ~~(~~of the Burano Formation~~),~~ which the basal detachment runs within its evaporitic interval (Ghisetti and Vezzani, 2000), Early to Late Jurassic platform and basinal limestones and dolostones (Calcare Massiccio, Corniola, Rosso Ammonitico, Calcari a Posidonia and Calcari ad Aptici Formations), and Cretaceous to Early Miocene basinal carbonates (Maiolica, Marne a Fucoidi, Scaglia and Biscaro Formations). In general, the lower part of Burano Formation is overlaid by the fluvio-deltaic siliciclastics of the Verrucano Formation (Middle-Late Triassic) (Tongiorgi et al., 1977; Ghisetti and Vezzani, 2000; Tavani et al., 2008). Nevertheless, the existence of these siliciclastics in the Montagna dei Fiori area is not yet proved. Syn-orogenic deposits include Miocene marls and turbiditic sandstones (Marne con Cerrogna and Laga Formations) (Artoni, 2013 and references therein).

The deposition of the Calcare Massiccio Formation, dated as Hettangian-Sinemurian and with a total thickness varying between 300 to 700 m (Pialli, 1971), records an important extension pulse in the evolution of Tethyan rifting. The following facies are observed in the lower part of the

Calcare Massiccio Formation: oncoid-rich peloidal pack- to grainstones in alternation with peloidal wacke- to packstones including horizons of algal bindstones (Calcare Massiccio A; Brandano et al., 2016). The upper part is made up of beds of skeletal and coated grain wacke- to grainstones including microoncoids, echinoderms, calcareous and siliceous sponges, bivalves, gastropods and ammonites (Calcare Massiccio B; Brandano et al., 2016). The lower part has been interpreted as having been deposited in a peritidal environment, while the upper part corresponds to lower to middle shelf depositional environments, characterized by a general deepening upward trend associated with extensional faulting and drowning of the platform, coupled with subsidence and deposition of the overlying Corniola Formation in the pelagic areas. Overall, the Early Jurassic rifting led to the growth of the Calcare Massiccio Formation in a carbonate platform setting, followed by faulting and drowning, and development of pelagic intrabasins filled by syn-rift sediments (Fig. 1c; Bernoulli et al. 1979; Santantonio and Carminati, 2011). The syn-rift deposits include pelagic limestones of the Bugarone and Corniola Formations. Condensed pelagic limestones of the Bugarone Formation (Lower Pliensbachian-Lower Tithonian; Bugarone Group in Pierantoni et al., 2013) occur at the top of the Calcare Massiccio Formation where it formed fault-controlled highs marking the regional drowning of the carbonate platform (Santantonio and Carminati, 2011). While, the pelagic limestones of the Corniola Formation (Sinemurian-Toarcian; Colacicchi et al., 1975; Morettini et al., 2002; Bosence et al., 2009; Marino and Santantonio, 2010; Brandano et al., 2016) occur within the fault-controlled (half)grabens in lateral continuation with the Calcare Massiccio Formation. The Corniola Formation in the lower part consists of turbiditic lobes originated from tectonic brecciation of the Calcare Massiccio Formation, and at the upper part is a well-bedded pelagic mudstone with chert nodules (Di Francesco et al., 2010). ~~In the Montagna dei Fiori, the geologic framework of the outcropping Calcare Massiccio Formation is still a matter of debate between a fault-related tectonosedimentary pattern (Mattei, 1987; Storti et al., 2017b), and a gravity-driven, olistolith hypothesis (Di Francesco et al, 2010; Santantonio et al., 2017). However, recent~~ Recent detailed work in the Salinello valley (Storti et al., 2017a; 2018) documented that major outcrops of Calcare Massiccio are bounded by mostly ~ E-W and ~ N-S striking fault zones showing extensional kinematics and dominantly affecting the Jurassic rocks older than the Maiolica Formation (Fig. ~~2A~~2a, e.g. sites 1 to 4). Overprinting relations indicate that ~ E-W deformation structures are systematically younger than the ~ N-S ones. Similar trends were observed in syn-

rift fault zones in other anticlines of the Central Apennines (e.g. Cooper and Burbi, 1986; Alvarez, 1989; Chilovi et al., 2002). Such a tectonosedimentary inheritance was involved in the growth of the Montagna dei Fiori Anticline, which initiated during the Late Miocene (Mazzoli et al., 2002; Artoni, 2003) and progressively evolved into the upper thrust sheet of a well-developed antiformal stack until Plio-Pleistocene times (e.g. Ghisetti et al., 1993; Calamita et al., 1994; Artoni, 2013). A major structural feature trending parallel to the Montagna dei Fiori Anticline and dissecting it is the Montagna dei Fiori Fault, a NNW-SSE striking extensional fault system cutting at high angle through the folded footwall rocks, typically at the forelimb-crest transition (Figs. 1, 2). This fault consists of two partially overlapping main fault zones with an extensional stratigraphic separation exceeding 900 m, and ~~This fault system~~ juxtaposes intensely deformed Late Miocene sediments in the hanging wall, against dolomitized and undolomitized Lower Jurassic and Cretaceous limestones in the footwall (Figs. 1 and 2). The development of the Montagna dei Fiori Fault has been alternatively interpreted as either a pre- (e.g. Calamita et al., 1994, Mazzoli, 2002; Scisciani et al., 2002) or late-folding (Ghisetti and Vezzani, 2000) feature. More recently, the origin of the Montagna dei Fiori Fault has been ascribed to the mutual interaction between horizontal shortening and uplift, and episodic gravitational re-equilibration during antiformal stacking underneath the anticline during Plio-Pleistocene times (Storti et al., 2018).

3 Methodology

The stratigraphic and deformational features of dolostones were analyzed in more than 60 outcrops. The distribution of dolomitized intervals as well as their cross-cutting relationships with bedding planes, stylolites, veins and structures were ~~ground-truthed~~documented and sampled. For petrographic analyses, 130 polished thin sections were studied with standard petrographic methods (transmitted and UV-fluorescent light microscopy). Dolomite crystal morphology and texture is based on the classification proposed by Sibley and Gregg (1987).

The rock slabs and thin sections were stained using Alizarine Red S and potassium ferricyanide (Dickson, 1966) to discriminate dolomite from calcite and evaluate their iron content. Cold cathodoluminescence microscopy (CL) was carried out on representative thin sections (n = 80) at KU Leuven University (Belgium) using a Technosyn cathodoluminescence device (8-15 kV, 200-400 μA gun current, 0.05 Torr vacuum and 5 mm beam width).

185 $\delta^{13}C$ and $\delta^{18}O$ analysis were carried out on 117 samples. Powder samples (150 - 200 µg)
186 were obtained by applying a New Wave Research micromilling device and a dental drill at KU
187 Leuven University (Belgium). The analysis was conducted at Parma University (Italy) and the
188 Friedrich-Alexander-Universität (Erlangen-Nürnberg, Germany) laboratories using Finnigan
189 DeltaPlus V and ThermoFinnigan 252 mass spectrometers, respectively. The carbonate powders
190 were reacted with 100% phosphoric acid at constant temperature of 75°C. Several additional CO_2
191 reference gases (NBS18, NBS19, MAB99, and a pure Carrara marble) with known isotopic ratio
192 were analyzed during the measurements to determine the $\delta^{13}C$ and $\delta^{18}O$ values of the sample.
193 Reproducibility was checked by replicate analysis of laboratory standards and was better than
194 ±0.1‰ for $\delta^{13}C$ and ±0.2‰ for $\delta^{18}O$ at Parma University and ±0.04 for $\delta^{13}C$ and ±0.05‰ for
195 $\delta^{18}O$ at Friedrich-Alexander-Universität. Oxygen isotope composition of dolomites was
196 corrected using the acid fractionation factors given by Rosenbaum and Sheppard (1986).
197 Duplicate homogeneous samples measured in both labs for inter-laboratory reproducibility ~~show~~
198 ~~$\delta^{13}C$ and $\delta^{18}O$ values within the acceptable range of error deviation (±0.1‰) both for $\delta^{13}C$ and~~
199 ~~$\delta^{18}O$~~. All carbon and oxygen values are reported in per mil, relative to the "Vienna PDB scale"
200 (V-PDB).
201 A total number of 21 samples were analyzed for their $^{87}Sr/^{86}Sr$ ratios. The analyses were
202 conducted at the Department of Analytical Chemistry, Ghent University (Belgium) and at the
203 Vrije Universiteit Amsterdam (the Netherlands). NIST SRM 987 was used as the international Sr
204 standard in both labs. At Ghent University, 15 sample powders (20 mg) were collected using a
205 dental drill device. The $^{87}Sr/^{86}Sr$ ratio measurements were performed using a Thermo Scientific
206 Neptune Multi-collector Inductively Coupled Plasma Mass Spectrometer (MC-ICP-MS)
207 instrument. Within the external precision, repeated analyses of the international Sr standard
208 yielded an average $^{87}Sr/^{86}Sr$ ratio of 0.710271 ± 0.000023 (2SD, n = 43), in agreement with the
209 accepted $^{87}Sr/^{86}Sr$ ratio of 0.710248 for this reference sample (Thirlwall, 1991). At Vrije
210 Universiteit Amsterdam, 6 sample powders (2 - 3 mg) were collected using a New Wave
211 Research micromilling device. Analyses were performed using a ThermoElectron Triton plus
212 TIMS instrument. In order to monitor and document the system's performance, repeated analyses
213 of the international Sr standard (n = 58) were carried out on load sizes of 10 ng and 100 ng which
214 yielded average $^{87}Sr/^{86}Sr$ ratios of 0.710245±0.000022 (2SD) and 0.710242±0.000008 (2SD),
215 respectively. In both labs mass discrimination correction was performed via internal

normalization using Russell's exponential law and the accepted value (0.1194; Steiger and Jager, 1977) of the invariant $^{86}Sr/^{88}Sr$ ratio.

Fluid inclusion microthermometry analysis was performed on 11 doubly polished wafers (80-130 μm in thickness). Measurements were carried out at Parma University (Italy) using Linkam THMSG-600 and Linkam MDS-600 heating-cooling stages coupled with a Leica DM 2500 microscope. The stages were calibrated by synthetic Syn Flinc™ fluid inclusion standards. A 100x objective was used during the microthermometry runs of the small inclusions. The microthermometry data were collected following the Fluid Inclusion Assemblage (FIA) approach described in Goldstein and Reynolds (1994) for carbonate minerals. The salinities are reported in equivalent weight percent NaCl (eq. wt. % NaCl) and were calculated based on the equation of Bodnar (1993).

In order to perform a high resolution petrography, Scanning Electron Microscope (SEM) and Back-scattered Scanning Electron Microscope (BSEM) analyses were conducted using a Jeol 6400 Scanning Electron Microscope (SEM) equipped with an Oxford EDS (Energy Dispersive System). Operating conditions were 15 kV and 1.2 nA, electron beam about 1 μm in diameter and 100 s counting time; errors are ±2-5% for major elements and ±5-10% for minor components. The analysis focused mainly on detecting possible dolomite crystals inside the bed perpendicular stylolites affecting the Cretaceous Scaglia Formation.

4 Results

4.1 Field observation and distribution of the dolomitized bodies

Dolomitization affected the Calcare Massiccio, Bugarone and Corniola Formations. There is no evidences of dolomitization in the overlying and immediate surrounding successions (e.g. Maiolica and Scaglia Formations), though the base of Maiolica Formation is reported as dolomitized in the Central Apennines onshore (e.g. Pierantoni et al., 2013) and offshore areas (Murgia et al., 2004). Dolomitized intervals are folded in the forelimb of the Montagna dei Fiori Anticline and are abruptly truncated by the Montagna dei Fiori Fault, which juxtaposes them against intensely foliated Scaglia, Bisciaro and Marne con Cerrogna Formations (Figs. 2 and 3). The distribution of dolomitized intervals is wider in the Salinello valley (Figs. ~~1B~~1b, ~~2A~~2a) perhaps due to a better exposure. In the Corano Quarry location, dolomitization occur in the Calcare Massiccio and Bugarone Formations only as meter-sized dolostone geobodies in the footwall of the Montagna dei Fiori Fault (Fig. 4).

Dolostone breccias in fault cores is typically clast-supported, with angular and millimeter- to centimeter-sized fragments (Fig. 3C), changing to crackle breccia (Woodcock and Mort, 2008) away from the master slip surface. In the proximity of the master slip surface, dolostone fragments are sporadically ~~overprinted~~ cross-cut by millimeter-sized dolomite veins. The breccia fragments, where cemented, are commonly surrounded by calcite.

Dolomitization does not follow a systematic pattern. The lateral extend of dolomitization is gradual. In some outcrops, dolomitization fronts show irregular outlines following, but also cross-cutting, the bedding surfaces (Fig. 5). ~~-~~Dolomitized intervals vary in thickness from few meters to hundred meters affecting the totality of the exposed Calcare Massiccio and only the lower part of Corniola Formation, where no clay interlayers are present. Dolomitized intervals in the Corniola Formation have a darker color relative to the host rock and are systematically more fractured than the hosting limestone. High amplitude (> 1 mm) bed-parallel stylolites are clearly visible in both limestones and dolostones (Fig. 5). However, in some dolostones only ghosts of stylolite traces can be seen. The dolostones locally contain porosity, appearing as millimetre- to centimetre-sized pores.

4.2 Petrography

4.2.1 Early calcite cementation

The early diagenetic products in the studied intervals are generally non-ferroan calcite cements. The first calcite cements precipitated following a phase of bioclast micritization (*sensu* Bathurst, 1975) in grain supported intervals. In chronological order, they include: 1) fibrous cements (FC) riming the bioclasts, mostly in the peloidal facies of the Calcare Massiccio Formation (Fig. ~~6A~~6a). These cements are ~~dull~~ dark brown to non-luminescent under cathodoluminescence; 2) mosaic cements (MC), commonly fill the intergranular pore spaces (Fig. ~~6B~~6b), and also occur as syntaxial overgrowths on echinoderm fragments. These cements exhibit deformation twining and show well-developed ~~dull~~ brown and orange concentrically-zoned cathodoluminescence pattern (Figs. ~~6C~~ 6c and ~~D~~d). They contain only mono-phase all-liquid inclusions. All of these cements are postdated by high amplitude bed-parallel stylolites.

4.2.2 Dolomitization

All the dolomite types are non-ferroan and dominantly fabric destructive. Dolomitization developed in all the facies types of the Calcare Massiccio and the overlaying Bugarone

Formations, but only at the lower part of the Corniola Formation which consists of resedimented Calcare Massiccio breccias (turbiditic lobes). The two first dolomite types (D1 and D2) are the dominant dolomite types in the studied outcrops. These dolomites are distributed within the damage zones of the ~ N-S and E-W Jurassic rift-related extensional faults and, in places, displaced by them (Fig. ~~2A~~2a, site 1). The third and fourth dolomite types (D3 and D4) are mainly observed within the damage zone of the Montagna dei Fiori Fault (NNW-SSE), and appear only as dolomitic pockets overprinting D1 and D2 at the proximity of the ~ N-S and E-W extensional faults. The fifth dolomite type (D5) is found only within the brecciated zones associated with the Montagna dei Fiori Fault damage zone. The distinctive petrographic features of the recognized dolomite types are summarized below:

Dolomite 1 (D1) is a replacive dolomite which commonly appears as dispersed rhombs and aggregates, and locally rims fracture walls cemented by calcite ~~(CV1)~~ (Figs. ~~6E~~ 6e and ~~F~~f). D1 postdates the micritic envelopes and early calcite cements, and predates high amplitude bed-parallel stylolites (Figs. ~~6G~~ 6g and ~~H~~h). The crystals are fine to medium sized (< 350 µm) ~~and~~ with planar-e and planar-s textures, ~~consists~~ consisting of relatively turbid, solid-inclusion rich, well-developed ~~euhedral to subhedral~~ crystals~~,~~. They show ~~with~~ red luminescence~~,~~ occasionally developing a concentrical zonation.

Dolomite 2 (D2) is a replacive dolomite (Figs. ~~7A~~ 7a and ~~B~~b), infrequently occluding existing pore spaces. Like D1, it also ~~frequently~~ predates high amplitude bed-parallel stylolites (Figs. ~~6G~~ 6g and ~~H~~h). D2 generally exhibits a ~~tightly~~ closely packed texture with no or little intercrystalline porosity. The crystals are medium to coarse sized (≤ 500 µm) with planar-s to non-planar textures. They includ~~ing~~ a turbid core followed by a transparent ~~subhedral to anhedral~~ rim and trace quantities of saddle dolomite developing swiping extinction. In some crystals one additional turbid zone rich in solid and fluid inclusions is present. Cathodoluminescence observations enabled to recognize the presence of D1 in their turbid cores. D2 crystals are characterized by zones of bright red-pink luminescence separated by purple luminescence zones (Fig. 7b).

Dolomite 3 (D3) is present as small localized bodies in the Calcare Massiccio (at the Castel Manfrino reference section), in the Corniola Formation (at the Osso Caprino Road), and in the Calcare Massiccio and Bugarone Formations (at the Corano Quarry). In the Corano Quarry the dolomitized Bugarone and Calcare Massiccio Formations are in the footwall of the Montagna dei

Fiori Fault; and juxtaposed to the undolomitezed, intensely foliated Scaglia Formation (the hanging wall). Within the Bugarone Formation in this fault damage zone, D3 locally cements the millimeter-sized angular breccias that are in turn affected by fault parallel stylolites (Figs. ~~7C~~ 7c and ~~D~~d). The SEM and BSEM analysis performed on the samples from the immediate adjacent Scaglia Formation within the aforementioned fault damage zone did not indicate the presence of any dolomite in this formation. D3 crystals are fine to medium sized (< 300 µm) ~~mostly transparent euhedral to anhedral~~exhibiting planar-e to non-planar textures ~~(< 300 µm)~~, with minor development of saddle morphologies ~~in~~ of larger crystals (> 500 µm) with planar-c texture (Figs. ~~7E~~ 7e to ~~H~~h). The ~~euhedral to anhedral~~replacive crystals ~~are generally replacive,~~ display~~ing~~ a faint core, which compared to previous dolomite types has fewer solid inclusions. The saddle crystals are occasionally replacive ~~but majorly appear as cement in fractures~~. They display typical curved and slightly serrated crystal terminations with swiping extinction. These saddle dolomites were only observed in the Castel Manfrino reference section. D3 generally exhibit a ~~dull~~ dark purple color with bright orange zones and subzones in core and/or rims when viewed under cathodoluminescence (Figs. ~~7E~~ 7e to ~~H~~h).

Dolomite 4 (D4) appears as a matrix replacive and dolomite cement surrounding porosity, and locally ~~recrystallizing~~ replacing D1 and D2 (Figs. ~~8A~~ 8a to ~~F~~f). D4 also occludes bed parallel shear fractures and appears along the bed parallel stylolites (Figs. ~~9A~~ 9a to ~~D~~d). In the Castel Manfrino reference section, some intercrystalline vuggy porosity is filled with fine dolomite rhombs including D4 with relics of D2 within their core (Figs. ~~8E~~ 8e and ~~F~~f). The porosity may be preserved or partially to completely filled by CV4. D4 crystals have a turbid, solid-inclusion rich core and transparent rim. They are fine to medium sized (< 200-350 µm), presenting ~~subhedral~~ planar-s ~~to~~ and infrequent ~~euhedral crystals~~non-planar textures. D4 exhibits a distinct luminescence pattern including a purple zone and an irregular green subzone.

Dolomite 5 (D5) occurs as crystals cementing micro-veins that cross-cut precursor dolomite types including dolomitic breccia fragments. In cemented breccias, D5 is postdated by CV3. D5 presents a planar-c texture ~~is transparent, anhedral~~ and is characterized by a bright red luminescence (Figs. ~~9E~~ 9e and ~~F~~f).

4.2.3 Late calcite cementation

Four generations of calcite veins postdating dolomitization have been identified (Figs. 10 and 11): 1) Calcite vein 1 (CV1) occurs only in Calcare Massicio limestones and is represented

as centimeter-sized veins that their thickness does not exceed 1.5 cm. These veins are strata-bound, bedding-perpendicular ~~veins~~ with irregular fracture walls, exhibiting white color in the outcrops. They postdate the first dolomite type (D1) riming the same fractures that abut the high amplitude bed parallel stylolites. CV1 often show blocky to elongated crystal morphologies and displays well-developed deformation twinning planes (Type II of Burkhard, 1993). This calcite exhibits concentrical zonation and ~~dull~~ brown zones alternate with orange luminescence zones (Figs. ~~11A~~ 11a and ~~B~~b). 2) Calcite vein 2 (CV2) exclusively occurs in the intensely deformed Scaglia Formation within the fault damage zones and correspond to tension gashes associated with stylolites (*sensu* Nelson, 1981). Their thickness does exceed 1 cm. They are often discontinuous and branch to several microveins (thickness < 1mm) when their tips are not intersected by stylolites. CV2 veins are mostly recorded in foliated shear deformation zones with well-defined S-C fabrics, exhibiting blocky, elongated to fibrous shapes with strongly developed tightly spaced deformation twinning planes (Type II of Burkhard, 1993). CV2 displays ~~yellow~~ brown to orange luminescence with locally darker sector zones. The ~~yellow~~ brown to orange luminescence characteristic of CV2 is comparable with those of encasing Scaglia host rocks (Figs. ~~11C~~ 11c and ~~D~~d). 3) Calcite vein 3 (CV3) occurs as cement, filling the extensional faults master plane and isolated veins within ~~the extesional fault~~their damage zones. These veins are centimeter-sized with thicknesses of less than 2 cm. CV3 cements the brecciated fault-infillings containing angular fragments of host rock limestones, dolostones and earlier calcites. In the brecciated fault zones at the backlimb of the anticline (Montagna dei Fiori Fault), CV3 always passively overgrows D5 in fractures and never cuts it.~~postdates the last dolomitization phase (D5) with no evidence of physical disruption.~~ CV3 exhibits a translucent white ~~to translucent~~ color in hand specimen. The crystals are blocky with no or weakly developed deformation twinning planes, and are characterized by a dark orange to brown luminescence with distinct darker sector zones (Figs. ~~11E~~ 11e and ~~F~~f). 4) Calcite vein 4 (CV4) exists as centimeter-sized isolated veins, pore-filling as well as breccia cements postdating all the preceding dolomites and calcites. The breccia fragments are more often dolostones. CV4 has a translucent white ~~to translucent white~~ color in hand specimen with blocky crystal morphology and no evidence of subsequent deformation (e.g. deformation twining planes), and is characterized by distinct concentrical zonation (Figs. ~~11G~~ 11g and ~~H~~h).

4.3 Geochemistry

4.3.1 Carbon and oxygen stable isotopes

The carbon and oxygen stable isotopic data ($\delta^{13}C$ and $\delta^{18}O$) of host rocks, dolomites and calcites are given in Table 1 and shown in Figures ~~12A~~ 12a and ~~B~~b. The marine stable isotopic compositions reported by Veizer et al. (1999) were used as marine reference values. Accordingly, Lower Jurassic marine limestones are characterized by $\delta^{13}C$ values of -0.5 to +4.5‰ and $\delta^{18}O$ values of -2.5 to +1.0‰ V-PDB. The $\delta^{18}O$ values of the marine dolomites are known to be 3-4‰ V-PDB more enriched than those of co-genetic marine limestones (Land, 1980; Major et al., 1992; Horita, 2014). Both $\delta^{13}C$ and $\delta^{18}O$ values of the host rocks are within the expected range of the Lower Jurassic marine limestones but the Corniola host rocks show slightly lower values comparing to those of Calcare Massiccio. In the Calcare Massiccio host rocks, the $\delta^{13}C$ values plot between +2.4 and +3.1‰ and $\delta^{18}O$ values are within the range of -1.6 and 0.0‰ V-PDB. The $\delta^{13}C$ values in the Corniola host rocks are +2.0 and +2.5‰ while the $\delta^{18}O$ values are -3.1 to -1.4‰ V-PDB. The $\delta^{13}C$ and $\delta^{18}O$ values of the Scaglia host rocks range between +1.0 to +3.3‰ for $\delta^{13}C$ and -2.2 to -1.0‰ V-PDB for $\delta^{18}O$. The obtained values are characterized in the mean range of Upper Cretaceous to Paleogene marine limestones (Veizer et al., 1999; +1.0 to +4.5‰ for $\delta^{13}C$ and -4.0 to +2.0‰ V-PDB for $\delta^{18}O$).

The $\delta^{13}C$ values of CV1 are between +1.6 and +2.1‰ which plot within the range of reference values (Jurassic) but are slightly lower than the surrounding host rock values. The $\delta^{18}O$ values are between -4.7 and -2.7‰ V-PDB which are lower than those of reference and host rock values.

The $\delta^{13}C$ values of all dolomite types (+0.6 to +3.4‰) fall within the range of host rocks and Jurassic marine limestones (Veizer et al., 1999). The $\delta^{18}O$ shows a wider range of values, somehow overlapping but also lower than ~~those of~~ host rocks (-4.5 to -0.9‰ V-PDB) and those expected for the ~~presumable~~ Lower Jurassic marine dolomites. The majority of values plot between -3.5 and -1.5‰ V-PDB. The small size and overgrowth nature of certain dolomite types (e.g. D2 and D5) limits their proper isolation for geochemical analyses. Only one sample from D1 dolomite could be measured for $\delta^{13}C$ and $\delta^{18}O$ values, showing +2.5 and -1.9‰ V-PDB, respectively. The $\delta^{13}C$ and $\delta^{18}O$ values of D3 dolomite range from +2.0 to +2.6‰ and -2.8 to -1.9‰ V-PDB, respectively, with values lower than those of the host rock.

D4 dolomite has $\delta^{13}C$ values between +2.4 and +2.5‰, and $\delta^{18}O$ values of -3.0 to -2.5‰ V-PDB. The $\delta^{13}C$ and $\delta^{18}O$ values of CV2 are +1.2 to +3.1‰ and -1.7 to -1.7‰ V-PDB,

respectively. The $\delta^{13}C$ values of CV3 are between +0.5 and +2.4‰, and the $\delta^{18}O$ values cover a range of -2.2 to 0.0‰ V-PDB. The $\delta^{13}C$ and $\delta^{18}O$ values of CV4 are +3.8 to +4.9‰ and -9.4 to -9.1‰ V-PDB, respectively. The $\delta^{13}C$ values are slightly higher but the $\delta^{18}O$ values are considerably lower compared to preceding calcite generations and the measured values from host rocks.

4.3.2 $^{87}Sr/^{86}Sr$ ratios

Samples from host rocks (i.e. Calcare Massiccio and Corniola Formations), dolomites (D1, D3 and D4) and the Scaglia Formation in juxtaposition with the dolostones were analyzed for their $^{87}Sr/^{86}Sr$ isotopic ratios. The obtained ratios versus $\delta^{18}O$ values of the analyzed samples are shown in Fig. 12C. The $^{87}Sr/^{86}Sr$ ratios obtained from the Calcare Massiccio and Corniola limestones are 0.70766 and 0.70725 (n = 2), respectively, which is in agreement with the values of the Lower Jurassic marine carbonates (0.70704-0.70768) reported by McArthur et al. (2012). CV1 show a value equal to 0.70773.

All the dolomite types display higher $^{87}Sr/^{86}Sr$ ratios when compared to the host rocks and reference values of the Lower Jurassic marine carbonates. D1 (replacive) and D4 cements show a comparable narrow range with values between 0.70784 and 0.70790, respectively. ~~While, the~~ The two D3 samples (replacive and cement) display higher $^{87}Sr/^{86}Sr$ ratios (0.70858 and 0.70963, respectively). The $^{87}Sr/^{86}Sr$ ratios obtained for dolomites do not show co-variation with corresponding $\delta^{18}O$ values. The radiogenic Sr analysis was not performed on D2 and D5 since the physical mixing with other dolomite types could not be avoided.

The $^{87}Sr/^{86}Sr$ ratios of the two marly limestone samples of Scaglia Formation are 0.70784 to 0.70790. The CV2 veins in Scaglia Formation show comparable ratios of 0.70779 and 0.70787. These values fit within the limits of values assigned by McArthur et al. (2012) for the Cenomanian-Bartonian (Scaglia age) marine carbonates (0.70730-0.70790).

4.4 Fluid inclusion microthermometry

The overview of microthermometry measurements is given in Table 1 and Figs. 13A to C. All the measured fluid inclusions are primary and occur in growth zones. Based on optical and fluorescence microscopy analysis of wafers all the inclusions are aqueous mono-phase (liquid) and two-phase (liquid and vapor) with relatively consistent L:V ratio of 10-15% within a single FIA (fluid inclusion assemblage).

~~On the basis of optical microscopy analysis of wafers,~~ D1 contain dominantly mono-phase aqueous inclusions with sizes greater than 5 µm. It is common for small inclusions (< 3 µm) to remain mono-phase all liquid at room temperature due to their metastability (Goldstein and Reynolds, 1994). Thus, to eliminate the possible role of metastability, the samples were placed in a freezer for several days following the procedures described in detail by Goldstein and Reynolds (1994). All liquid inclusions remained unchanged and no vapor bubble was developed within them, which discards the metastability effect. In order to properly observe the phase transitions and determine the final melting temperature of ice in the all liquid inclusions, they were rapidly heated up to ~ 200°C to stretch and nucleate a bubble at room temperature (Goldstein, 1990). All the inclusions froze at -65 to -49°C. The first melting (Te) was detected between -22 to -19.3°C. The final ice melting (Tm) appeared at temperatures between -7.7 and -2°C. Applying Bodnar´s (1993) equation, the obtained final melting temperatures correspond to salinity ranges of 3.5 to 11.3 eq. wt. % NaCl.

D2 is characterized by the presence of mono-phase and infrequent two-phase inclusions generally within their growth zones. The homogenization temperature of two-phase inclusions varies between 58 and 71°C. Upon cooling, a complete freezing of the fluid phase is reached at -56 to -40°C. The first ice melting temperature was distinguished at -22°C. The final ice melting temperatures fall within -17.5 and -5°C, corresponding to salinities between 7.9 and 20.5 eq. wt. % NaCl.

D3 is commonly inclusion poor. The measureable inclusions were detected and examined only in saddle dolomite crystals. These crystals contain only two-phase aqueous inclusions. Their homogenization temperatures are within the narrow range of 70 to 73°C. The complete freezing and first ice melting temperatures could not be distinguished but the final ice melting temperature occurred at temperatures between -13 and -6°C equal to salinity ranges of 9.2 to 16.9 eq. wt.% NaCl. The first melting temperatures of fluid inclusions in D1, D2 and D3 were about -21°C, suggesting a H_2O-NaCl fluid system.

D4 contains only two-phase aqueous inclusions. The homogenization temperatures in D4 vary between 79 and 105°C. Complete freezing of inclusions occurred at temperatures between -86 and -54 °C. The first ice melting was detected at -35 to -40°C indicating the possible presence of divalent cations such as Ca^{2+} and/or Mg^{2+} in the fluids (Shepherd et al., 1985; Goldstein and Reynolds, 1994). The final ice melting temperatures fall within a range

of -15 and -9°C corresponding to salinities of 12.8 to 18.6 eq. wt. % NaCl. A couple of inclusions show homogenization temperatures exceeding 120°C with salinities higher than 20 eq. wt. % NaCl. The inconsistent homogenization temperatures and salinities obtained for these fluid inclusions, within the framework of an individual fluid inclusion assemblage (FIA) described by Goldstein and Reynolds (1994), indicate possible re-equilibration of these inclusions and thus are not used in the interpretations.

The obtained homogenization temperatures in all fluid inclusion assemblages indicate the minimum temperatures at which the fluids could have been trapped (Goldstein and Reynolds, 1994). No correction was made for pressure effects on entrapment temperatures since no data regarding the exact depth and pressure of entrapment are available. In absence of independent thermal indicators such as Conodont Alteration Index (CIA) and Vitrinite Reflectance (VR), the accuracy of pressure correction cannot be well constrained (Slobodník et al, 2006), and thus no correction was made for pressure effects on homogenization temperatures.

No measurable fluid inclusion could be identified in CV1 and CV2 due to intense deformation twinning. CV3 and CV4 contain only primary mono-phase aqueous inclusions, indicating an entrapment temperature of below about 40-50°C (Goldstein and Reynolds, 1994). A complete freezing of the inclusions in CV3 occurred at temperatures between -40 and -52.5°C. The first melting temperature was detected at about -21 to -22°C, suggesting a H_2O-NaCl composition. The final melting temperatures range between -6.4 and -2.7°C, corresponding to salinities between 9.7 and 4.5 eq. wt. % NaCl. The majority of the values cluster between 7.8 and 5 eq. wt. % NaCl.

The complete freezing temperatures of the inclusions in CV4 fall within -46 and -35.5°C. The first melting temperature could not be determined with confidence but the final melting temperatures were reached at about -0.1 to -1.8°C, corresponding to salinities of 0.17 to 3.0 eq. wt. % NaCl.

5 Discussion

5.1 Stable and radiogenic isotopic composition of the parental fluids

The $\delta^{13}C$ values of all dolomite types mimic the range of host rock and Jurassic marine limestones and, consequently, they can be interpreted as largely rock-buffered. Their $\delta^{18}O$ values are partly comparable to those of their respective host rocks as well as Jurassic marine reference values but more depleted when compared to the presumable Jurassic marine dolomites. The

493 relatively depleted $\delta^{18}O_{dolomite}$ values could indicate the contribution of heated fluids in
494 dolomitization process, although it could also relate to recrystallization of a precursor dolomite
495 by fluids at higher temperature or ^{18}O-depleted (Land, 1980; 1985). The absence of distinctive
496 textural evidence in the analyzed samples such as enlarged crystal size and/or systematic mottled
497 cathodoluminescence pattern, and their co-variation with $\delta^{18}O$ values do not confirm
498 recrystallization (Mazzullo, 1992 and ref. therein). Nevertheless, special care was taken to avoid
499 the samples that occasionally displayed scattered mottled luminescence.

500 The oxygen isotope fractionation relation between water and dolomite (Land, 1983) was
501 used to determine the most plausible parental fluids. In order to avoid erroneous results due to
502 rock-buffered $\delta^{18}O$ values, only the $\delta^{18}O$ values of dolomite cements, especially from the bed
503 parallel veins containing D4 were used. These values may provide the closest approximation to
504 the $\delta^{18}O$ signature of the parental fluids (Barker and Cox, 2011). Accordingly, a $\delta^{18}O$ value of ≈
505 +2.5 to +4‰ V-SMOW was calculated for D3, while this values increase to ≈ +5 to +7.5‰
506 V-SMOW for D4 (Fig. ~~13D~~13d). ~~The calculated compositions of the potential parental fluids are~~
507 ~~progressively higher~~ The higher $\delta^{18}O$ composition of the dolomitizing fluids relative to the
508 Mesozoic seawater, which is estimated at -1.2 to -1‰ V-SMOW (Shackleton and Kennett, 1975;
509 Marshall, 1992; Saelen et al., 1996), is compatible with fluids derived from or that had interacted
510 with siliciclastics, crystalline basement (Taylor, 1997) and/or evaporite-derived brines.

511 The $^{87}Sr/^{86}Sr$ ratios obtained for all dolomite types are higher than the Lower Jurassic
512 marine carbonate values (0.70704-0.70768; McArthur et al., 2012). Since marine carbonates
513 have very low rubidium (Rb) concentrations they produce negligible *in situ* radiogenic ^{87}Sr after
514 their deposition (Stueber et al. 1972; Burke et al. 1982). Therefore, the higher $^{87}Sr/^{86}Sr$ ratios can
515 be explained by the contribution of fluids originated or interacted with potassium rich
516 siliciclastics (K-feldspars), crystalline basement and/or stratigraphic levels with higher $^{87}Sr/^{86}Sr$
517 ratios (Emery and Robinson 1993; Banner, 2004). Taking into account that the Upper Triassic
518 Burano Formation underlying the studied intervals as the basal detachment has $^{87}Sr/^{86}Sr$ ratios
519 between 0.70774 and 0.70794 (Boschetti et al., 2005), the $^{87}Sr/^{86}Sr$ ratios (D1 and D4) can
520 partially be explained by their contribution. However, this contribution cannot justify much
521 higher $^{87}Sr/^{86}Sr$ ratios recorded in D3, being higher than values reported for Phanerozoic
522 seawater (McArthur et al., 2012), and the values recorded in adjacent basinal deposits (i.e.
523 Corniola and Scaglia Formations). Therefore, parental fluids most likely originated from or had

interacted with the siliciclastics underlying the Burano Formation (Verrucano Formation), if present, and/or with the crystalline basement with common elevated $^{87}Sr/^{86}Sr$ ratios (0.71500-0.72650; Del Moro et al., 1982). The lack of any ferroan diagenetic phase minimizes the intreaction of fluids produced by clay transformation/dewatering (i.e. smectite to illite transformation; Boles and Franks, 1979).

CV1 is characterized by $\delta^{13}C$ and $\delta^{18}O$ values lower than the host limestones (i.e. Calcare Massiccio), while its $^{87}Sr/^{86}Sr$ ratio is comparable to them. The salinity and composition of the parental fluids cannot be inferred here since no measurable fluid inclusions were found within this cement. The $^{87}Sr/^{86}Sr$ ratio being within the range of the corresponding host rocks and the reference values, points to a rock-buffered system for $^{87}Sr/^{86}Sr$.

The $\delta^{13}C$ and $\delta^{18}O$ values obtained for CV2, as well as $^{87}Sr/^{86}Sr$ ratios, fall within the range of the Scaglia host rocks, thus reflecting their rock-buffered nature. This interpretation is further supported by the comparable luminescence characteristics of CV2 with that of encasing Scaglia host rocks. The fluids from which CV2 calcite precipitated, as expected for tension gashes, were most likely derived from carbonate dissolution during pressure-solution and stylolitization~~.~~, pointing to a closed fluid system in contrast with the subsequent vein generations.

CV3 is characterized by $\delta^{13}C$ values within the Jurassic marine values but are generally lower than the host rocks, while their $\delta^{18}O$ values partially overlap both the hosting limestones and dolostones. Microthermometry of fluid inclusions revealed only mono-phase aqueous inclusions and thus precipitation at relatively low temperature ($\leq$ 40-50°C) with moderate salinity (4.5-9.7 eq. wt. % NaCl). Such levels of salinity can be assigned to evaporated seawater, residual brines or fluids derived from evaporite dissolution, and thus makes it difficult here to interpret their exact origin with the available data.

CV4 is the latest calcite phase, and records the $\delta^{13}C$ and $\delta^{18}O$ values, respectively enriched and significantly depleted when compared to their hosting rocks and preceding diagenetic products. Generally, the enrichment of ^{13}C could suggest CO_2 outgassing due to evaporation or pressure changes (Friedman, 1970; Hendry et al., 2015) or bacterial fermentation (methanogenesis) of organic matter (Hudson, 1977) in low temperature diagenetic environments. The homogenization temperature of CV4 being below about 40-50°C could support any of these processes. Their low $\delta^{18}O$ values and fluid inclusions with salinities comparable to, but also

significantly lower than, seawater reflect the contribution of meteoric fluids during precipitation of this calcite.

5.2 Origin of the dolomitizing fluids

The contribution of brines that derived from highly evaporated seawater or evaporites is suggested by the elevated salinity values obtained from microthermometry of the fluid inclusions (3.5 to 20.5 eq. wt. % NaCl). Accordingly, two sources that could potentially provide such fluids can be proposed: 1) fluids related to the Late Messinian evaporites (Upper Miocene), associated with the overlying Laga Formation, ~~deposited during the Upper Miocene time,~~ and their possible downward percolation through fault zones by density driven flow and/or seismic pumping mechanisms (Sibson, 1981; McCaig, 1988, 1990); or their tectonic involvement into the Apenninic thrust wedge during its propagation (underthrusting; Lobato et al., 1983); and 2) fluids related to the underlying ~~décollement~~ detachment horizon of the Burano evaporites (Upper Triassic) and their upward flow through fault zones during development of the Montagna dei Fiori Anticline. The first scenario is valid if the dolomitization would have occurred only from the Upper Miocene time onwards. Moreover, ~~Several~~ several researchers (e.g. Vai and Ricci Lucchi, 1977; Bassetti et al., 1998; Roveri et al. 2001) have shown that the occurrence of primary shallow-water evaporites, which were dominantly gypsum, was limited only to the western and central parts of the northern Apennines consisting of thrust-top marginal basins~~. In contrast, evaporites never precipitated in parts of the central Apennines including the Montagna dei Fiori region (Marche area)~~ (Roveri et al. 2001). Hence, the evaporitic horizons existing within the Laga Formation corresponds to resedimentation (gypsum debris) of those previously precipitated in the marginal basins. This interpretation makes the Messinian evaporites an unlikely source of Mg-rich brines. ~~Moreover, taking~~ Taking into account that the maximum burial related temperature of the Calcare Massiccio Formation did not exceed 80°C in the Montagna dei Fiori region (Ronchi et al., 2003), it's not likely that the downward percolation of relatively low-temperature brines derived from the Messinian evaporites~~, located at the higher stratigraphic levels~~, could reach or exceed the high temperatures recorded in fluid inclusions of the studied dolomites ~~in the Calcare Massiccio Formation~~ (D4; up to 105°C), given that the homogenization temperatures reflect the minimum entrapment temperatures (Goldstein and Reynolds, 1994). Deep circulation of these brines, if existed, can also be excluded by their

limited ~~tectonic~~ involvement within the thrust wedge being confined merely to the off shore wards of the Montagna dei Fiori region (Artoni, 2013).

Accordingly, the Upper Triassic Burano Formation, the basal detachment, appears as the most plausible source for the high salinity brines recorded in fluid inclusions, and likewise, the Mg-rich fluids could have been originated from post-evaporite brines associated with them (Carpenter, 1978; McCaffrey et al., 1987). The fluctuations in salinity may argue for ~~different degrees of~~ diverse range of fault connectivity, different degrees of rock-water interaction and contribution of pore waters of lower salinity (e.g. marine or meteoric).

5.3 Timing and structural controls on the evolution of parental fluids

A generalized paragenesis and the relative chronology of dolomitization in relation to the structural evolution of the Montagna dei Fiori Anticline are illustrated in Figs. 14 and 15. The paragenesis is constructed on the basis of direct evidences recorded during observations at outcrop scale and microscopic observations (e.g. cross-cutting relationships between diagenetic phases, stylolites, fractures and other structural kinematics), and indirect evidences (e.g. regional geodynamics and burial history).

The occurrence of micritic envelopes and fibrous calcite cements (FC), in grain supported stratigraphic levels of the Calcare Massiccio Formation, is interpreted to be of eogenetic origin (i.e. marine phreatic diagenesis; Moore, 1989), reflecting an early diagenesis shortly after deposition. The well-developed ~~dull~~ brown and orange concentric cathodoluminescence pattern of the succeeding mosaic calcite cement (MC) suggests a progressive shift to more reducing conditions during precipitation in a phreatic diagenetic environment (as shown in Li et al., 2017). High amplitude bed parallel stylolites postdate both cements, which confirm their precipitation before significant burial. The observations made here are in agreement with earlier work by Giacometti and Ronchi (2000), interpreting that the Calcare Massiccio Formation was cemented during the early diagenetic stages.

D1, CV1 and D2 are postdated by well-developed, high amplitude bed-parallel stylolites. Presence of D1 and CV1 in bed-perpendicular veins typically abutted by these stylolites (see Figs. ~~6E~~ 6e to ~~H~~h) support the interpretation that the first dolomitization event (D1 and D2) took place before significant burial and stylolite development~~, .~~ ~~being t~~The latter and bed-perpendicular veins are dynamically compatible within the same stress field which is characterized by a vertical, load-related maximum principal axis of the stress ellipsoid. The

dominantly mono-phase fluid inclusions within D1 and D2 are in agreement with precipitation temperatures below about 40-50°C, suggesting a relatively shallow to intermediate burial environment and hence supporting a pre-Apenninic orogeny age of precipitation from a mix of formational and extra-formational fluids with elevated $^{87}Sr/^{86}Sr$ ratios. The distribution of D1 and D2 localized nearby the rifting-related ~ N-S and E-W striking extensional faults and even their displacement along them (Fig. ~~2A~~2a, e.g. site 1), point to the possible contribution of these faults in occurrence of D1 and D2. These faults dominantly affect the Jurassic rocks older than the Maiolica Formation which is attributed to the post-rift deposits, therefore suggesting a pre-Maiolica age for these dolomite types. Although, an absolute age cannot be provided, based on the evidence discussed above, the circulation of Mg-rich fluids during this dolomitization event was most likely controlled by rifting-related Jurassic extensional fault zones cutting through the crystalline basement. Precipitation of D1 and D2 at the lower part of Corniola Formation which is known as the syn-rift deposit discards a pre-rift origin for these dolomites. The displacement of dolomites along the aforementioned faults is possibly related to their prolonged activation during Early to Late Jurassic. In addition to the role of these faults in channelizing the fluids, their mobilization must have been intensified by some deriving mechanisms. A thermal convection system derived from high hit flux during rifting was interpreted by Hollis et al. (2017) to be responsible for circulation of seawater in a syn-rift dolomitization case in the Hammam Faraun fault block (Suez Rift, Egypt). In such scenario, the salinity of the fluids and their $^{87}Sr/^{86}Sr$ ratios are expected to be more or less within the range of seawater. Furthermore, this scenario seems unlikely in the studied area given the lack of a deep aquifer to accommodate the fault tips and promotes the lateral fluid flux from basin to the rift shoulders and vice versa. Taking into account that D1 and D2 are the volumetrically more relevant dolomites within the studied intervals, and assuming the likely role of syn-rift extensional faults (Early to Late Jurassic) in their precipitation, a dominantly syn-rift dolomitization process is proposed for the dolostones in the Montagna dei Fiori Anticline. Although, the CL zonation pattern observed in D2 may indicate changes in flow condition or fluid composition, the lack of physical disruptions such as multiple fracturing suggests external regional controls rather than slip along the same faults (Eichhubl and Boles, 2000). The absence of pervasive syn-dolomitization fracturing and brecciation as well as zebra fabrics in these dolomites, perhaps indicate a relatively calm tectonic period during dolomite development (e.g. Hollis et al., 2017).

D3 and D4 both record elevated $^{87}Sr/^{86}Sr$ ratios which accounts for their fault-controlled origin. However, their occurrence at the top of the Calcare Massiccio and overlaying Bugarone Formation (Corano Quarry site) which is < 1 m thick in Montagna dei Fiori region, and is marked as the final rift deposit (Cardello and Doglioni, 2015) discards a syn-rift origin for these dolomites. Moreover, D3 and D4 postdate the development of high amplitude bed parallel stylolites. The formation of stylolites requires an approximate overburden of 600 to 1500 m (Lind, 1993; Machel, 1999; Mountjoy et al., 1999; Schulz et al., 2016), corresponding to a late to post-Maiolica deposition time (Early Cretaceous time onwards). The presence of D3 and D4 dolomites in bed parallel fractures and shear veins (D4) suggests their association with contractional deformations, i.e. the most likely tectonic regime for explaining bed-perpendicular dilation. Therefore, the volumetrically minor second stage of dolomite precipitation may possibly be related to the Late- to post-Miocene compressional tectonics recorded in this region (e.g. Mazzoli et al., 2002; Artoni, 2013; Storti et al., 2018).

Dolostones containing D3 and D4 appear commonly as clast-supported breccias along fault zones pertaining to the Montagna dei Fiori Fault, then overprinted by fault-parallel stylolites. Accordingly, the occurrence of these dolomites was probably synchronous with the incipient stages of fault development, predating fault buttressing (Storti et al., 2018). Homogenization temperatures recorded in D4 (up to 105°C), much higher than the maximum temperatures recorded in the host rocks (below about 80°C; Ronchi et al., 2003), suggest hydrothermal fluid circulation. The development of the Montagna dei Fiori Anticline at the toe of the Late Miocene Central Apennines thrust wedge could have favored the forelandward migration of hydrothermal fluids expelled from the more internal regions of the belt, similarly to what has been proposed for the Rocky Mountains foreland (i.e. squeegee flow model; Machel and Cavell, (1999). Such a migration may have possibly favored the precipitation of D4 in bed parallel veins, generally considered as evidence for syn-compressional fluid overpressure (Sibson, 2001; Hiemstra and Goldstein, 2015). At this stage, in addition to dilation of the pre-existing ~ N-S and E-W striking rift-related extensional faults and their possible role in fluid migration, the excess of pore pressure at the base of the thrust ramp, in the fold hinge and during fold tightening could promote the localization of the fractures (Smith and Wiltschko, 1996; Ghisetti and Vezzani, 2000), with fluid migration within this zone and eventually dolomitization. These fractures could have been corridors that later on formed the insipient NW-SE Montagna

dei Fiori Fault, and their localization at the back-limb cross-cutting the core, explaining best the distribution of D3 and D4 at this locality. The presence of D5 only within the damage zone of the Montagna dei Fiori Fault, postdating dolostone brecciation and, in places, cementing breccia fragments, may suggest that D5 dolomite precipitation was associated with the late stage evolution of the Montagna dei Fiori Fault, predating late stage calcite precipitation.

The presence of several generations of bed perpendicular stylolites bounding and intersecting CV2 veins, supports that late stage calcite cements precipitated closely associated with the deformation history of the Scaglia Formation in the hanging wall of the Montagna dei Fiori Fault, during buttressing against Calcare Massiccio and Corniola Formations in the footwall, and related with the positive inversion event induced by thrust-sheet stacking at depth (Storti et al., 2018). Precipitation of CV3 and CV4 in interpreted to have occurred during uplift and cooling as revealed by their relatively low homogenization temperatures (≤ 40-50°C). Deformation twining is either absent or weakly developed, reflecting the lack of significant tectonic deformation after calcite precipitation. These cements postdate the dolomitization events, high amplitude bed perpendicular and parallel stylolites, and are precipitated as cements bounding the breccia fragments within the damage zone of the Montagna dei Fiori Fault. Salinities calculated from their fluid inclusions, particularly in CV4 suggests precipitation from meteoric waters, which should have been favored during the late evolutionary stages of antiformal stacking beneath the Montagna dei Fiori Anticline, and eventual late extensional slip along the Montagna dei Fiori Fault (Storti et al., 2018). The results obtained in this study are in relative agreement with the earlier work by Ronchi et al. (2003) and Murgia et al. (2004) in the Central Apennines, assigning dolomitization phases to the pre- and syn-orogenic deformations, although they did not specify the direct relation between the local structures and the different types of dolomite.

Although, the texture of the studied dolomites vary from planar-e to non-planar, the preponderance of planar dolomite, as in D4, creates a rock with interesting poroperm characteristics (e.g. Woody et al., 1996; Wilson et al., 2007; Wenzhi et al., 2012). This case-study is certainly relevant for many potential reservoirs elsewhere in the world. Similar multistage burial dolomitization events enhancing the reservoir quality have been reported from the carbonate successions of the Jurassic in the Kopet-Dagh Basin, north eastern Iran (Adabi, 2009) and Devonian of the Rainbow sub-Basin, western Canada (Qing and Mountjoy, 1989; Lonnee, 1999).

6 Conclusions

The Lower Jurassic limestones outcropping at the core of the Montagna dei Fiori Anticline (Central Apennines, Italy) are massively affected by dolomitization, in damage zones of the pre-orogenic faults inherited from the Tethyan rifting and the ones formed during the Apenninic orogeny. Cross-cutting relationships between deformation structures, and results from optical and cold cathodoluminescence petrography, fluid inclusion microthermometry, and isotope geochemistry, support the occurrence of two major dolomitization events. The first event is interpreted as developed during the late stages of Tethyan rifting in Jurassic and resulted in volumetrically significant dolostone geobodies. These dolostones are majorly matrix replacive and their precipitation initiated prior to the significant burial as reflected in their cross-cutting relationship with bed parallel stylolites, and by homogenization temperatures in fluid inclusions that are dominantly below about 40-50°C. The second dolomitization event corresponds to volumetrically less relevant replacive dolomite and dolomite cements occluding fractures. These dolomites precipitated during hydrothermal fluid circulation associated with contractional tectonics during the Apenninic orogeny, possibly at the onset of the growth of the Montagna dei Fiori Anticline (Late Miocene).

Dolomitizing fluids in both events were most likely sourced from evaporitic brines associated to the underlying Burano evaporites and their interaction with siliciclastics and/or the crystalline basement.

Author contributions. M. Mozafari participated in fieldwork, performed petrographic and microthermometric analyses, provided their interpretation, and wrote the manuscript; R. Swennen participated in fieldwork, discussed the results of the diagenetic study, and critically reviewed the manuscript; F. Balsamo contributed to collect and interpret structural data, discussed structural diagenesis data interpretation, and critically reviewed the manuscript; H. El Desouky collected $^{87}Sr/^{86}Sr$ data; F. Storti conceived the research, contributed to collect and interpret structural data, discussed structural diagenesis data interpretation, and critically reviewed the manuscript; C. Taberner participated in fieldwork, discussed the results of the diagenetic study and their framing into the proposed structural evolution, and critically reviewed the manuscript.

Acknowledgments. This research was performed by collaboration between Parma and KU Leuven universities in the framework of a research project (PT12432 and GFSTE 1100942) funded by Shell Global Solutions International (Carbonate Research Team, now Geology and New Reservoir Types Team). We thank E.M. Selmo (Parma University) and M. Joachimski (University of Erlangen, Germany) for the stable carbon and oxygen analysis. G. Davis (VU Amsterdam, the Netherlands) is thanked for the strontium isotope analysis. A. Comelli and H. Nijs are kindly thanked for the careful preparation of the wafers and thin sections. L. Barchi is gratefully appreciated for his help in SEM analysis. We gratefully acknowledge A. Koopman for the constructive discussions during field work.

Table captions

Table. 1. Stable carbon and oxygen isotopes, $^{87}Sr/^{86}Sr$ ratios, and fluid inclusion microthermometry data (not pressure corrected) of host rocks and diagenetic phases in the Montagna dei Fiori Anticline. Stable carbon and oxygen isotopes values are expressed in ‰ V-PDB and salinity values in eq. wt. % NaCl.

Figure captions

Fig. 1. ~~A~~a) Simplified regional map (modified after Ghisetti and Vezzani, 1997) showing the tectonic outlines of the Central Apennines and the study area (rectangle). ~~B~~b) Schematic

geological map of the Montagna dei Fiori Anticline showing the distribution of dolostones (modified after Storti et al., 2017a). ~~C~~c) Lithostratigraphical column of the successions exposed in Montagna dei Fiori (modified after Mattei, 1987; Di Francesco et al, 2010; Storti et al., 2018). Letter *B* stands for the Bugarone Formation. Lithologies are mentioned in the text. Note that the thickness of the not-outcropping formations (Triassic evaporites and the crystalline basement) is not to scale. ~~D~~d) Geological transect across present day Central Apennines and the Adriatic Sea (modified after Fantoni and Franciosi, 2010) with vertical exaggeration of 2:1. The dashed rectangle indicates the Montagna dei Fiori Anticline region.

Fig. 2. ~~A~~a, ~~B~~b) Geological map of the central sector of the Montagna dei Fiori Anticline, and cross-section oriented parallel (a-b) to the hinge line representing the tectono-stratigraphic architecture of the faulted anticline (modified after Storti et al., 2017a). The stereonets (Schmidt equal area projection lower hemisphere) provide the attitude of the extensional faults. The locations of the corresponding field sites are indicated by ~~numbers~~letters. c) At this location, well exposed N-S striking extensional fault zones offset the dolomitized Corniola Formation. The fault zone is characterized by near-horizontal stylolites localized in the footwall damage zone (4 fault data). d, e and f) These locations consist of mostly ~ E-W striking extensional fault zones. Particularly evident are the boundary fault zones delimiting Calcare Massiccio in the main horst block (site d: 20 fault data; site e: 24 fault data; site f: 9 fault data). g and h) At these locations, dip-slip slickenlines support major extensional movements related to the Montagna dei Fiori Fault. Contractional deformation structures are preserved in the bed-perpendicular stylolites, shear surfaces and tension gashes arranged as S-C arrays (site g: 21 fault data; site h: 14 fault data). Equal area projection, lower hemisphere.

Fig. 3. ~~A~~a) Field photograph showing the deformed Scaglia Formation in the hanging wall (HW) and brecciated, dolomitized Calcare Massiccio Formation in the footwall (FW) of the Montagna dei Fiori Fault. ~~B~~b) A hand specimen from the deformed Scaglia formation showing the intensity of the pressure solutions (TS) and their abutting relationship with calcite veins (CV2). ~~C~~c) A transmitted light photomicrograph of the dolomitized, brecciated Calcare Massiccio Formation. Note all the breccia fragments are composed of dolomite (D4 here).

Fig. 4. Field photographs (Corano Quarry) showing the field relations between dolostones, host limestones and the Montagna dei Fiori Fault: ~~A~~a) Panoramic view showing the spatial relationship between limestones and dolostones (orange) in the damage zone of the Montagna dei Fiori Fault (F). Note that the limestones and including dolostones of the Calcare Massiccio and Bugarone Formations on the footwall (FW) and marly limestones of the Scaglia Formation on the hangingwall (HW) are intensely deformed. ~~B~~b) Plan view of the Calcare Massiccio limestone in the footwall damage zone: intersected by calcite veins (CV1), dolomitized and affected by bed perpendicular stylolites (arrows). ~~C~~c) Distinct transition (dashed line) between dolomitized and undolomitized Calcare Massiccio limestone in the footwall damage zone.

Fig. 5. Field photograph (~~A~~a) and a simplified sketch (~~B~~b) of a dolomitic pocket within the folded Calcare Massiccio (grey color) and their relation with bed parallel stylolites (hammer is 40 cm long).

Fig. 6. ~~A~~a) Transmitted light image showing a micritic peloid rimmed by the fibrous cements (FC) which are followed by the mosaic cements (MC). ~~B~~b) Transmitted light image showing mosaic cements (MC) in a peloidal limestone over printed by high amplitude bed parallel stylolites (dotted white line). Note the core of some of the peloids is partially cemented as well. ~~C~~c, ~~D~~d) Respectively, transmitted light and corresponding cathodoluminescence image of FC and MC cements. ~~E~~e) Transmitted light photomicrograph showing D1 crystals rimming a fracture which is cemented by CV1. The fracture is in turn affected by a bed parallel stylolite. ~~F~~f) Cathodoluminescence image showing D1 scattered in the host rock and riming the fracture. ~~G~~g, ~~H~~h) Respectively, transmitted light and corresponding cathodoluminescence image showing part of a bed parallel stylolite (dotted white line) overprinting D1 and D2 crystals.

Fig. 7. ~~A~~a, ~~B~~b) Photomicrographs of respectively, transmitted light and corresponding cathodoluminescence image showing the zoned rhombs of D2 with the remnants of D1 preserved in their cloudy core. The pore space is occluded by D4. ~~C~~c, ~~D~~d) D3 cementing angular breccia fragments of the Bugarone Formation in the damage zone of the Montagna dei Fiori Fault in the Corano Quarry site. Note the breccia is overprinted by a fault parallel bed perpendicular stylolite. ~~E~~e, ~~F~~f) Photomicrographs of respectively, transmitted light and corresponding

cathodoluminescence image showing the euhedral to subhedral crystals of D3 developing a bright subzone and rim. ~~G~~g, ~~H~~h) D3 with a saddle crystal outline (SD) postdating calcite cements (MC) and a zoned D2 crystal. The saddle morphology is outlined by a dotted white line.

Fig. 8. Photomicrographs of respectively, transmitted light and corresponding cathodoluminescence image of dolomite types: ~~A~~a, ~~B~~b) The cross-cutting relationship between D3 and D4. Note the presence of D3 within the core of dolomite crystals overgrown by D4. ~~C~~c, ~~D~~d) Successions of dolomite types. Note the green CL color of D4 crystals. Typically, luminescent dolomites are known to show yellow, orange to red colors (Machel et al., 1991). Green luminescence in carbonates including dolomite have been attributed by a number of researchers to the incorporation of three valent rare earth elements (REE) such as Dy^{3+} and U^{3+} as luminescence activators within their crystal lattice (Luczaj and Goldstein, 2000). Another possibility is the emplacement of Mn^{2+}, with yellow luminescence, in Ca^{2+} sites with blue luminescence in the dolomite crystal lattice instead of preferential incorporation in the Mg^{2+} site (Sommer, 1972b; Amieux, 1982; Walker et al., 1989; Habermann et al., 1999). Accordingly, non-stoichiometric, Ca-rich and poorly ordered dolomites may favor Mn^{+2} incorporation into their Ca^{2+} site. ~~E~~e, ~~F~~f) Vuggy porosity rimmed by D4 (green CL). Note the porosity is filled with fine dolomite rhombs including traces of D2 in their core and D4 overgrowths.

Fig. 9. Photomicrographs showing respectively, transmitted light and corresponding cathodoluminescence image of D4 and D5 in relation to stylolites and fracturing: ~~A~~a, ~~B~~b) D4, exploiting a bed parallel stylolite that crossed-cuts D1 and D2. ~~C~~c, ~~D~~d) A sub-horizontal fracture cemented by D4. ~~E~~e, ~~F~~f) D5 microveins (arrows) intersecting all the predating dolomite types in the footwall brecciated zone of the Montagna dei Fiori Fault.

Fig. 10. Field photographs showing the major calcite vein settings observed in Montagna dei Fiori: ~~A~~a) Cross-sectional view of bed normal Calcite vein 1 (CV1) abutting bed parallel stylolites in folded beds of the Calcare Massiccio Formation. ~~B~~b) Plan view of the Calcite vein 2 (CV2) intensely affecting the deformed Scaglia (Rossa) Formation. ~~C~~c, ~~D~~d) Cross-sectional view of the Scaglia Formation, intensely affected by pressure solution seams of tectonic origin

crossed-over by populations of bed-perpendicular Calcite veins (CV3) in en echelon extensional arrays.

Fig. 11. ~~A~~a) Cathodoluminescence and transmitted light (in set) image showing blocky to elongated crystals of CV1 with zoned CL pattern. ~~B~~b) Transmitted light image showing intensely twinned CV1 crystals overprinted by euhedral to subhedral crystals of D3. Photomicrographs of respectively, transmitted light and corresponding cathodoluminescence image: ~~C~~c, ~~D~~d) CV2 in the Scaglia Formation abutted by a bed perpendicular stylolite (indicated by white arrows and dashed line). The crystals display blocky to fibrous morphologies, deformation twining, and a similar orange luminescence pattern comparable with the adjacent host rock. ~~E~~e, ~~F~~f) CV3 cementing the breccia fragments in the damage zone of the Montagna dei Fiori Fault. The crystals are blocky and show faint deformation twinning. They are brown-orange with distinct darker luminescence sector zones. ~~G~~g, ~~H~~h) CV4 present as a cement within a polygonal pore space rimmed by dolomite. Note the blocky crystals, absence of deformation twinning and distinct concentric luminescence zonation pattern. CV4 is corroded and followed by a late telogenetic calcite.

Fig. 12. ~~A , B)~~ Overview of the $\delta^{13}C$ and $\delta^{18}O$ values of dolomites (~~A~~a) host rocks from Montagna dei Fiori as well as calcite veins (~~B~~b). The stable isotope value of Lower Jurassic marine limestones based on Veizer et al. (1999) is indicated by a dashed rectangle in subset B. The $\delta^{18}O$ values of the marine dolomites are considered to be 3-4‰ V-PDB higher than those of marine limestones (Land, 1980; Major et al., 1992; Horita, 2014). ~~C~~c) Cross-plot of $^{87}Sr/^{86}Sr$ ratios and corresponding $\delta^{18}O$ values of host rocks, dolomites and calcite veins compared with Lower Jurassic marine carbonates $^{87}Sr/^{86}Sr$ (dashed rectangle) framework reported by McArthur et al. (2012).

Fig. 13. Overview of microthermometry analysis of primary inclusions in Montagna dei Fiori: ~~A~~a) Frequency distribution of the Tm_{ice} (°C) in dolomite phases. ~~B~~b) Frequency distribution of the Th (°C) in dolomite phases. ~~C~~c) Salinity (eq. wt. % NaCl) versus Th (°C) of dolomite and calcite phases. ~~D~~d) Isotopic fractionation diagram from Land (1983) used to determine the

isotopic composition (‰ V-SMOW) of parental fluids in equilibrium with dolomites in Montagna dei Fiori.

Fig. 14. ~~A)~~ Generalized paragenesis of diagenetic phases in relation to deformational stages and burial history of the Calcare Massiccio Formation in the Montagna dei Fiori Anticline. The deformational stages are from Storti et al. (2018), and the burial curve is based on Ronchi et al. (2003). The burial curve was made based on paleo-depth, paleo-temperatures, sedimentation rate and paleo- heat flow.

Fig. 15. Sketch showing the successive fault-related diagenetic phases, of most importantly dolomitization, recorded in the carbonate succession exposed at the core of the Montagna dei Fiori Anticline (not scaled). Different diagenetic phases are indicated with different colors. ~~A~~a) The first dolomitization event is pre-orogenic (syn-rift), triggered from the fluids channelized along Jurassic extensional faults. This event occurred during burial compaction and development of bed parallel stylolites (BS). It is represented by scattered dolomite rhombs (D1) followed by calcite cementation (CV1). The dolomitization continued with precipitation of larger crystals of D2. ~~B~~b) Second dolomitization event: syn-orogenic (early folding/ faulting) dolomitization from fluids that migrated from more internal regions of the thrust belt and were channelized along the basal detachment level into the fold core. This dolomitization event presents matrix replacive and cements displaying infrequent saddle outlines (SD) in pore spaces, within bed parallel veins and shear fractures. These dolostones postdate compaction but are affected by bed perpendicular stylolites (TS) generated by horizontal to sub-horizontal layer parallel shortening related to the growth of the Montagna dei Fiori Anticline. ~~C~~c) Extensional collapse of the anticline and development of the Montagna dei Fiori Fault, followed by buttressing of the Scaglia against Calcare Massiccio and Corniola Formations during positive inversion induced by continuing underthrusting at depth. Precipitation of D5 in micro-veins and cements in breccia zones, followed by late stage calcite cementation in the Montagna dei Fiori Fault damage zone (CV2, CV3 and CV4).

	Stable isotopes		Sr isotopes	Fluid inclusion microthermometry		
	$\delta^{13}C$	**$\delta^{18}O$**	**$^{87}Sr/^{86}Sr$**	**Th (°C)**	**Salinity**	**n**
Calcare Massiccio Fm.	+2.4 to +3.1	-1.6 to 0.0	0.70766	-	-
